Abstract

Systems biology provides a comprehensive approach to biomarker discovery and biological hypothesis building. Indeed, it allows to jointly consider the statistical association between gene variation and a phenotype, and the biological context of each gene, represented as a network. In this work, we study the utility of six methods that identify subnetworks with higher association scores to a phenotype to discover new biomarkers for breast cancer susceptibility. We interrogate a familial breast cancer genome-wide association study (GWAS) focused on *BRCA1/2* negative French women. We perform an in-depth benchmarking of the methods with regards to size of the solution subnetwork, their utility as biomarkers, and the stability and the runtime of the methods. By trading statistical stringency for biological meaningfulness, most network methods give more compelling results than standard SNP- and gene-level analyses, recovering causal subnetworks tightly related to cancer susceptibility. Interestingly, a combination of solution subnetworks provided a concise subnetwork of 93 genes, enriched in known breast cancer susceptibility genes (*BABAM1*, *BLM*, *CASP8*, *FGFR2*, and *TOX3*, Fisher's exact test P-value = 7.8×10^{-5}) and occupying more central positions in the network than average. Additionally, it shows a general alteration of the neighborhood of *COPS5*, a gene related to multiple hallmarks of cancer [CA: Update to talk about the stable consensus and *CUL3* instead...]. Finally, we find a significantly large overlap between the genes in the consensus network and the genes significantly associated in the largest GWAS on susceptibility to breast cancer. In conclusion, this article shows the pertinence of network-based analyses to tackle known issues with GWAS, namely lack of statistical power and of interpretable solutions. Project-agnostic implementations of each of the network methods are

available at <https://github.com/hclimente/gwas-tools> to facilitate their application to other GWAS datasets.

1 Introduction

In human health, genome-wide association studies (GWAS) aim at quantifying how single-nucleotide polymorphisms (SNPs) predispose to complex diseases, like diabetes or some forms of cancer [11]. To that end, in a typical GWAS thousands of unrelated samples are genotyped: the cases, suffering the disease of interest, and the controls from the general population. Then, a per-SNP statistical association test is conducted (e.g. based on logistic regression). Those SNPs with a P-value lower than a conservative Bonferroni threshold are candidates to further studies in an independent cohort. Once the risk SNPs have been discovered, they can be used for risk assessment, and to deepen our understanding of the disease.

GWAS have successfully identified thousands of variants underlying many common diseases [10]. However, this experimental setting also presents intrinsic challenges. Some of them stem from the high dimensionality of the problem, as every GWAS to date studies more variants than samples are genotyped. This limits the statistical power of the experiment, as only variants with larger effects can be detected [52]. This is particularly problematic since the prevailing view is that most genetic architectures involve many variants with small effects [52]. Additionally, to avoid false positives, a conservative multiple test correction is applied, typically the previously mentioned Bonferroni correction. However, Bonferroni correction is overly conservative when the statistical tests are correlated, as is the case in GWAS [54]. Another open issue is the interpretation of the results, as the functional consequences of most common variants are not well understood. On top of that, recent large-sampled studies suggest that most of the genome contributes to a degree to any complex trait, in accordance with the infinitesimal model [5]. The recently proposed omnigenic model [7] offers an explanation: genes are very functionally inter-related and influence each other's behavior, which allows alterations in most genes to impact the subset of "core" genes directly involved in the disease's mechanism. Hence, a comprehensive statistical framework which includes the structure of biological data might address the aforementioned issues.

For this reason, many authors turn to network biology to handle the complex interplay of biomolecules that lead to disease [21]. As its name suggests, network biology models biology as a network, where the biomolecules under study, often genes, are nodes, and selected functional relationships are edges that link them. These relationships come from evidence that the genes jointly contribute to a biological function; for instance, their expression is correlated, or their products establish a protein-protein interaction. Under this view, complex diseases are not the consequence of a single altered gene, but of the interaction of multiple interdependent molecules [4]. In fact, an examination of biological networks shows that disease genes have differential properties [4, 44]. This is particularly true for cancer driver genes, which tend to be key players in connecting different, densely-connected communities of genes. Additionally, as genes that contribute to a disease tend

to participate in similar biological functions, studying the neighborhood of known disease genes is effective at identifying new ones [26].

Network-based biomarker discovery methods exploit this relatedness to identify disease genes on GWAS data [2]. In essence, each SNP has a score of association with the disease, given by the experiment, and functionally biological relationships, given by a network built on prior knowledge. Then, the problem becomes finding a functionally-related set of highly-scoring genes. Different solutions have been proposed to this problem, often stemming from divergent mathematical frameworks and considerations of what the optimal solution looks like. Some methods strongly constrain the problem to certain kinds of subnetworks. Such is the extreme case of LEAN [24], which focuses on “star” subnetworks, i.e. instances where both a gene and its direct interactors are associated with the disease. Other algorithms, like dmGWAS [29] and heinz [19], focus on larger subnetworks interconnecting genes with high association scores. However, they differ in their tolerance to the inclusion of low-scoring nodes, and the topology of the solution. Lastly, other methods also consider the topology of the network, favoring groups of nodes that are not only high-scoring, but also densely interconnected; such is the case of HotNet2 [30], SConES [3], and SigMod [34].

In this work, we analyze the effectiveness of these six network methods for biomarker discovery on GWAS data. While all of them capture susceptibility mechanisms resembling that postulated by the omnigenic model, they do so in different ways, and provide a representative view of the field. We worked on the GENESIS dataset [51], a study on familial breast cancer conducted in the French population. After a classical GWAS approach, we use these network-based methods to recover additional breast cancer biomarkers. Lastly, we carry out a comparison of the solutions obtained by the different methods, and aggregate them to obtain a consensus network of predisposition to familial breast cancer.

2 Methods

2.1 GENESIS

The GENE Sisters (GENESIS) study was designed to investigate risk factors for familial breast cancer in the French population [51]. Index cases are patients with infiltrating mammary or ductal adenocarcinoma, who had a sister with breast cancer, and who have been tested negative for *BRCA1* and *BRCA2* pathogenic variants. Controls are unaffected colleagues and/or friends of the cases, born around the year of birth of their corresponding case (± 3 years). We focused on the 2577 samples of European ancestry, of which 1279 are controls and 1298 are cases. The genotyping was performed using the iCOGS array, a custom Illumina array designed to study genetic susceptibility of hormone-related cancers [48]. It contains 211 155 SNPs, including SNPs putatively associated with breast, ovarian, and prostate cancers, SNPs associated with survival after diagnosis, and SNPs associated to other cancer-related traits, as well as functional candidate variants in selected genes and pathways.

2.2 Preprocessing and quality control

We discarded SNPs with a minor allele frequency lower than 0.1%, those not in Hardy–Weinberg equilibrium in controls (P -value < 0.001), and those missing on more than 10% of the samples. A subset of 20 duplicated SNPs in *FGFR2* were also removed. In addition, we removed the samples with more than 10% missing genotypes. After controlling for relatedness, 17 additional samples were removed (6 for sample identity error, 6 controls related to other samples, and 3 additional controls having a high relatedness score). Lastly, based on study selection criteria, 11 other samples were removed (1 control having cancer, 4 index cases with no affected sister, 3 half-sisters, 1 sister with lobular carcinoma *in situ*, 1 with a *BRCA1/2* mutation detected in the family, 1 with unknown molecular diagnosis). The final dataset included 1 271 controls and 1 280 cases, genotyped over 197 083 SNPs.

We looked for population structure that could produce spurious associations. A PCA revealed no visual differential population structure between cases and controls (Supplementary Figure 1). Independently, we did not find evidence of genomic inflation ($\lambda = 1.05$) either, further confirming the absence of confounding population structure.

2.3 High-score subnetwork search algorithms

2.3.1 SNP and gene association

To measure association between a genotype and the phenotype, we performed a per-SNP 1 d.f. χ^2 allelic test using PLINK v1.90 [13]. Then, we used VEGAS2v2 [38] to compute the gene-level association score from the P -values of the SNPs mapped to them. Specifically, for each gene we only used the 10% of SNPs mapped to it with lowest P -values. We mapped SNPs to genes through their genomic coordinates: all SNPs located within the boundaries of a gene, ± 50 kb, were mapped to that gene. We used the 62 193 genes described in GENCODE 31 [20], although only 54 612 could be mapped to at least one SNP. Out of those, we focused exclusively on the 32 767 that had a gene symbol. Out of the 197 083 SNPs remaining after quality control, 164 037 were mapped to at least one of these genes.

We used such mapping to compare the outputs of methods that produce SNP-lists to those that produce gene-lists, and vice versa. For the former, we considered any gene that can be mapped to any of the selected SNPs as selected as well. For the latter, we considered all the SNPs that can be mapped to that gene as selected by the method.

2.3.2 Mathematical notations

In this article, we use undirected, vertex-weighted networks, or graphs, $G = (V, E, w)$. $V = \{v_1, \dots, v_n\}$ refers to the vertices, with weights $w : V \rightarrow \mathbb{R}$. Equivalently, $E \subseteq \{\{x, y\} | x, y \in V \wedge x \neq y\}$ refers to the edges. When referring to a subnetwork S , V_S is the set of nodes in S

and E_S is the set of edges in S . A special case of subgraphs are *connected* subgraphs, which occur when every node in the subgraph can be reached from any other node.

In addition to a weight, nodes have other properties, provided by the topology of the graph. In this article we focus on two of those: degree centrality, and betweenness centrality. The degree centrality, or degree, is the number of edges that a node has. The betweenness centrality, or betweenness, is the number of times a node participates in the shortest paths between two other nodes.

In addition, we use several matrices that describe different properties of a graph. The described matrices are square, and have as many rows and columns as nodes are in the network. The element (i, j) represents a selected relationship between v_i and v_j . The *adjacency matrix* W_G contains a 1 when the corresponding nodes are connected, and 0 otherwise; the diagonal is zero. The *degree matrix* D_G is a diagonal matrix which contains the degree of the different nodes.

2.3.3 Networks

Gene network The statistical frameworks of the different network methods are compatible with any type of network (protein interactions, gene coexpression, regulatory, etc.). Yet, we used protein-protein interaction networks (PPIN) for all of them except SConES, as they are interpretable, well characterized, and they were designed to scale appropriately to them. We built our PPIN from both binary and co-complex interactions stored in the HINT database (release April 2019) [16]. Unless otherwise specified, we used only interactions coming from high-throughput experiments, leaving out targeted studies that might bias the topology of the network. Out of the 146 722 interactions from high-throughput experiments that HINT stores, we were able to map 142 541 to a pair of gene symbols, involving 13 619 genes. 12 880 of those mapped to a genotyped SNP after quality control, involving 127 604 interactions. The scoring function for the nodes changed from method to method (Section 2.3.4).

Additionally, we compared the results of the aforementioned PPIN with those obtained on another PPIN built using interactions coming from both high-throughput and targeted studies. In that case, out of the 179 332 interactions in HINT, 173 797 mapped to a pair of gene symbols. Out of those, 13 735 mapped to a genotyped SNP after quality control, involving 156 190 interactions.

SNP networks SConES [3] is the only network method designed to handle SNP networks. As in gene networks, two SNPs are linked in a SNP network when there is evidence of shared functionality between two SNPs. Azencott et al. [3] proposed three ways of building these networks: connecting the SNPs consecutive in the genomic sequence (“GS network”); interconnecting all the SNPs mapped to the same gene, on top of GS (“GM network”); and interconnecting all SNPs mapped to two genes for which a protein-protein interaction exists, on top of GM (“GI network”). We focused on the GI network, as it fits the scope of this work better, using the PPIN described above. However, at different stages of this work we also used GS and GM for comparison. For the GM network, we used the mapping described in Section 2.3.1. In all three the node scores are the

association scores of the individual SNPs with the phenotype (1 d.f. χ^2). The properties of these three subnetworks is available in Supplementary Table 1.

2.3.4 Network methods

Table 1: Summary of the differences between the network methods.

Method	Field	Nodes	Exhaustive	Solution	Comp.	Input	Scoring	Ref.
dmGWAS	GWAS	Genes	No	-	1	Summary	$-\log_{10}(P)$	[29]
heinz	Omics	Genes	Yes	-	1	Summary	BUM	[19]
HotNet2	Omics	Genes	Yes	Module	≥ 1	Summary	Local FDR	[30]
LEAN	Omics	Genes	Yes	Star	≥ 1	Summary	$-\log_{10}(P)$	[24]
SConES	GWAS	SNPs	Yes	Module	≥ 1	Genotypes	1 d.f. χ^2	[3]
SigMod	GWAS	Genes	Yes	Module	≥ 1	Summary	$\Phi^{-1}(1 - P)$	[34]

Field: field in which the algorithm was developed. **Nodes:** the type of network, either gene (protein-protein interaction network usually) or a SNP network. **Exhaustive:** whether all the possible solutions given the selected hyperparameters are explored. **Solution:** additional properties are enforced on the solution subnetwork, other than being dense in high scores and connected. **Comp.:** number of connected components in the solution. **Input:** genotype data or GWAS summary statistics. **Scoring:** how SNP/gene P-values are transformed into node scores. In the case of SigMod, Φ^{-1} represents the inverse of the cumulative distribution function of the standard Normal distribution. **Ref.:** original publication featuring the algorithm.

Genes that contribute to the same function are nearby in the PPIN, might be topologically related to each other in diverse ways (densely interconnected modules, nodes around a hub, a path, etc.). But this is not the only aspect to model when developing a network method: how to score the nodes, whether the affected mechanisms form a single connected component or several, how to frame the problem in a computationally efficient fashion, which network to use, etc. Unsurprisingly, multiple solutions have been proposed. We examined six of them: five that explore the PPIN, and one which explores SNP networks. We selected methods that were open source, had an implementation available, and an accessible documentation. Their main differences are summarized in Table 1.

dmGWAS dmGWAS seeks the subgraph with the highest local density in low P-values [29].

To that end it searches candidate subnetwork solutions using a greedy, “seed and extend”, heuristic:

1. Select a seed node i and form the subnetwork $S_i = \{i\}$.
2. Compute Stouffer’s Z-score Z_m for the current subgraph S_i as

$$Z_m = \frac{1}{\sqrt{k}} \sum_{j \in S_i} z_j$$

where k is the number of genes in S_i ; z_j is the Z score of gene j , computed as $\phi^{-1}(1 - \text{P-value}_j)$; and ϕ^{-1} is the inverse normal distribution function.

3. Identify neighboring nodes of S_i , i.e. nodes at distance $\leq d$.
4. Add the neighboring nodes whose inclusion increases the Z_{m+1} more than a threshold $Z_m \times (1 + r)$.
5. Repeat 2-4 until no further enlargement is possible.
6. Add S_i to the list of subnetworks to return. Its Z-score is normalized as

$$Z_N = \frac{Z_m - \text{mean}(Z_m(\pi))}{\text{SD}(Z_m(\pi))}$$

where $Z_m(\pi)$ represents a vector containing 100 000 random subsets of the same number of genes.

DmGWAS carries out this process on every gene in the network. We used the implementation of dmGWAS in the dmGWAS 3.0 R package [55]. We used the suggested hyperparameters $d = 2$ and $r = 0.1$. We used the function *simpleChoose* to select the solution subnetwork, which aggregates the top 1% modules into the solution subnetwork.

heinz The goal of heinz is to identify the highest-scored connected subgraph on the network [19].

The authors propose a transformation of the genes' P-value into a score that is negative under no association with the phenotype, and positive when there is. This transformation is achieved by modelling the distribution of P-values by a beta-uniform model (BUM) parameterized by the desired false discovery rate (FDR). Thus formulated, the problem is NP-complete, and hence solving it would require a prohibitively long computational time. To solve it efficiently it is re-cast as the Prize-Collecting Steiner Tree Problem (PCST), which seeks to select the connected subnetwork S that maximizes the *profit* $p(S)$, defined as:

$$p(S) = \sum_{v \in V_S} p(v) - \sum_{e \in E_S} c(e).$$

were $p(v) = w(v) - w'$ is the *profit* of adding a node, $c(e) = w'$ is the *cost* of adding an edge, and $w' = \min_{v \in V_G} w(v)$ is the smallest node weight of G . All three are positive quantities. Heinz implements the algorithm from Ljubić et al. [35] which, in practice is often fast and optimal, although neither is guaranteed. We used BioNet's implementation of heinz [6, 18].

HotNet2 HotNet2 was developed to find connected subgraphs of genes frequently mutated in cancer [30]. To that end, it considers both the local topology of the network and the scores of the nodes. The former is captured by an insulated heat diffusion process: at initialization, the score of the node determines its initial heat; iteratively each node yields heat to its "colder"

neighbors, and receives heat from its “hotter” neighbors, while retaining part of its own (hence, *insulated*). This process continues until equilibrium is reached, and results in a diffusion matrix F . F is used to compute the similarity matrix E that models exchanged heat as

$$E = F \operatorname{diag}(w(V)),$$

where $\operatorname{diag}(w(V))$ is a diagonal matrix with the node scores in its diagonal. For any two nodes/genes i and j , E_{ij} models the amount of heat that diffuses from node j to node i , which can be interpreted as a (non-symmetric) similarity between those two nodes. To obtain densely connected subnetworks, HotNet2 prunes E , only preserving edges such that $w(E) > \delta$. Lastly, HotNet2 evaluates the statistical significance of the subnetworks by comparing their size to the size of networks obtained by permuting the node scores. We assigned initial node scores as in Nakka et al. [40], assigning a score of 0 for the genes with low probability of being associated to the disease, and $-\log_{10}(\text{P-value})$ to those likely to be. In this dataset, the threshold separating both was a P-value of 0.125, which was obtained using a local FDR approach [49]. HotNet2 has two parameters: the restart probability β , and the threshold heat δ . Both parameters are set automatically by the algorithm, which is robust to their values [30]. HotNet2 is implemented in Python [31].

LEAN LEAN searches altered “star” subnetworks, that is, subnetworks composed by one central node and all its interactors [24]. By imposing this restriction, LEAN is able to exhaustively test all such subnetworks (one per node). For a particular subnetwork of size m , the P-values corresponding to the involved nodes are ranked as $p_1 \leq \dots \leq p_m$. Then, k binomial tests are conducted, to compute the probability of having k out of m P-values lower or equal to p_k under the null hypothesis. The minimum of these k P-values is the score of the subnetwork. This score is transformed into a P-value through an empirical distribution obtained via a subsampling scheme, where gene sets of the same size are selected randomly, and their score computed. Lastly, P-values are corrected for multiple testing through a Benjamini-Hochberg correction. We used the implementation of LEAN from the LEANR R package [23].

SConES SConES searches the minimal, modular, and maximally associated subnetwork in a SNP graph [3]. Specifically, it solves the problem

$$\arg \max_{S \subseteq G} \underbrace{\sum_{v \in V_S} w(v)}_{\text{association}} - \lambda \underbrace{\sum_{v \in V_S} \sum_{u \notin V_S} W_{vu}}_{\text{connectivity}} - \underbrace{\eta |V_S|}_{\text{sparsity}} \quad (1)$$

where λ and η are hyperparameters that control the sparsity and the connectivity of the model. The connectivity term penalizes disconnected solutions, with many edges between a node that is selected and a node that is not. Given a λ and an η , the aforementioned problem has a unique solution, that SConES finds using a graph min-cut procedure. As in Azencott et al.

[3], we selected λ and η by cross-validation, choosing the values that produce the most stable solution across folds. In this case, the selected hyperparameters were $\eta = 3.51$, $\lambda = 210.29$ for SConES GS; $\eta = 3.51$, $\lambda = 97.61$ for SConES GM; and $\eta = 3.51$, $\lambda = 45.31$ for SConES GI. We used the version on SConES implemented in the R package `martini` [15].

SigMod SigMod aims at identifying the highest-scoring, most densely connected gene subnetwork [34]. It addresses an optimization problem similar to that of SConES (Equation 1), but the connectivity term encourages connected solutions by favoring solutions where many edges connect two selected nodes, rather than penalizing disconnected ones.

$$\arg \max_{S \in G} \underbrace{\sum_{v \in V_S} w(v)}_{\text{association}} + \lambda \underbrace{\sum_{v \in V_S} \sum_{u \in V_S} W_{vu}}_{\text{connectivity}} - \underbrace{\eta |V_S|}_{\text{sparsity}} .$$

As SConES, this optimization problem can also be solved by a graph min-cut approach.

SigMod presents three important differences with SConES. First it is designed for gene-gene networks. Second, it favors subnetworks containing many edges. SConES, instead, penalizes connections between the selected and unselected nodes. Third, it explores the grid of hyperparameters differently, and processes their respective solutions. Specifically, for the range of $\lambda = \lambda_{\min}, \dots, \lambda_{\max}$ for the same η , it prioritizes the solution with the largest change in size from λ_n to λ_{n+1} . Such a large change implies that the network is densely interconnected. This results in one candidate solution for each η , which are processed by removing any node not connected to any other. A score is assigned to each candidate solution by summing their node scores and normalizing by size. The candidate solution with the highest standardized score is the chosen solution. SigMod is implemented in an R package [33].

Consensus In addition, we built a consensus network by retaining the nodes that were selected by at least two of the six methods (using SConES GI for SConES).

2.4 Pathway enrichment analysis

We searched for pathways enriched in the gene subnetworks produced by the above methods. We conducted an hypergeometric test on pathways from Reactome [28] using the R package ReactomePA [57]. The universe of genes included any gene that we could map to a SNP in the iCOGS array (Section 2.3.1). Pathways with an adjusted P-value < 0.05 were deemed significant. As the significant pathways are often overlapping and redundant, the results were manually curated afterwards.

2.5 Evaluation of methods

We evaluated multiple properties of the different method through a 5-fold subsampling setting. We applied each method to 5 random subsets of the original dataset containing 80% of the samples (*train set*). When pertinent, we evaluated the solution on the remaining 20% (*test set*). We used the 5 repetitions to estimate the average and the standard deviation of the different measures.

2.5.1 Properties of the solution

We compared the runtime, the number of selected genes/SNPs, and the stability (sensitivity of the result to small changes in the input, here, using different subsets of the data) of the different network methods. The stability was quantified using the Pearson correlation to measure the overlap between different runs as suggested by Nogueira and Brown [43].

2.5.2 Classification accuracy of selected SNPs

A desirable solution offers good predictive power on unseen *test* samples. We evaluated the predicting power of the SNPs selected by the different methods through the performance of an L1-penalized logistic regression classifier, a machine learning algorithm that searches a small subset of SNPs which provide good classification accuracy. We trained the classifier exclusively on those selected SNPs to predict the outcome (case/control). The L1 penalty helps to account for LD by reducing the number of SNPs included in the model (*active set*), while improving the generalization of the classifier. This penalty was set by cross-validation, choosing the value that minimized misclassification error. We applied each network method to each *train* set, and trained the classifier on it as well using only on the selected SNPs. When the method retrieved a list of genes (all of them except SConES), we considered as selected all the SNPs mapped to any of those genes. Then we evaluated the sensitivity and the specificity on the *test set*. The active set gave an estimate of a plausible, more sparse solution with a comparable predictive power to the original solution. To obtain a baseline, we also trained the classifier on all the SNPs.

2.5.3 Comparison to state-of-the-art

An alternative way to evaluate the results is comparing our results to an external dataset. For that purpose, we recovered a list of 153 genes associated to familial breast cancer from DisGeNET [45]. Across this article we refer to these genes as *breast cancer susceptibility genes*.

Additionally, we used the summary statistics from the Breast Cancer Association Consortium (BCAC), a meta-analysis of case-control studies conducted in multiple countries which included 13 250 642 SNPs (after imputation) genotyped on 228 951 women of European ancestry from the general population [37]. Hence, a high proportion of breast cancer cases investigated in BCAC are sporadic, while GENESIS is a homogeneous dataset focusing on the French high-risk population attending the family cancer clinics. Despite these differences, we expect a shared genetic

architecture, especially at the gene level. For that purpose, we searched for associated genes as in Section 2.3.1. We used all the SNPs to measure gene association, but only those available after quality control on GENESIS for the SNP-level comparisons.

2.6 Code availability

We developed computational pipelines for several steps of GWAS analyses, such as physically mapping SNPs to genes, computing gene scores, and performing six different network analyses. For each of those processes, we created a pipeline with a clear interface that should work on any GWAS dataset. They are compiled in <https://github.com/hclimente/gwas-tools>. Although the GENESIS data is not public, the code to apply the pipelines to this data, as well as the code that reproduces all the analyses in this article are available at <https://github.com/hclimente/genewa>. We deposited all the produced gene subnetworks on NDEx (<http://www.ndexbio.org>), under the UUID e9b0e22a-e9b0-11e9-bb65-0ac135e8bacf.

3 Results

3.1 A conventional GWAS confirms that FGFR2 is associated with familial breast cancer

We conducted association analyses in the GENESIS dataset at both SNP and gene levels (Section 2.3.1). Two genomic regions have a P-value lower than the Bonferroni threshold in chromosomes 10 and 16 (Supplementary Figure 2A). The former overlaps with gene *FGFR2*; the latter with *CASC16*, and it is located near the protein-coding gene *TOX3*. Variants in both *FGFR2* and *TOX3* were related to breast cancer susceptibility in other case-control studies [37], *BRCA1/2* carriers studies [39], and in hereditary breast and ovarian cancer families negative for *BRCA1/2* [47]. Only *FGFR2* was significant at the gene-level (Supplementary Figure 2B). These results show an overlap in the genetic architecture of the disease between the studied French population sample and other populations.

Closer examination reveals two regions (3p24 and 8q24) having low, albeit not genome-wide significant, P-values. Both of them have been associated to breast cancer susceptibility in the past [9, 50]. We applied an L1-penalized logistic regression on the whole dataset (Section 2.5.2). It selected 100 SNPs, both from all aforementioned regions and from other regions (Supplementary Figure 2C). Yet, it is unclear why those SNPs were selected, as emphasized by the high P-value of some of them, which further complicates the biological interpretation. Moreover, and in opposition to what the omnigenic model predicts, the genes to which these SNPs map to (Section 2.3.1) are not interconnected in the PPIN (Section 2.3.3). In addition, the classification performance of the method is very low, and L1-penalized methods select only one of several correlated variables and are prone to instability, which further complicates interpretation. This motivates exploring network methods, which trade statistical significance for biological relevance to find susceptibility

subnetworks. In fact, such methods provided comparably (poor) classification performance to L1-penalized logistic regression (Figure 3B), while providing more interpretable solutions.

3.2 Network methods successfully identify genes associated with breast cancer

Table 2: Summary statistics on the solutions of multiple network methods on the gene-gene interaction network. The first row contains the summary statistics on the whole network.

Network	# genes	# edges	Betweenness	\hat{P}_{gene}	$\rho_{\text{consensus}}$
HINT HT	13 619	142 541	16 706	0.46	0.066
Consensus	55	117	74 062	0.0051	1
dmGWAS	194	450	49 115	0.19	0.41
heinz	4	3	113 633	0.0012	0.21

SConES GI	0 (1)	0	-	-	-
SigMod	142	249	92 603	0.0083	0.73

genes: number of genes selected out of those that are part of the PPIN; for SConES GI the total number of genes, including RNA genes, was added in parentheses. Betweenness: mean betweenness of the selected genes in the PPIN. \hat{P}_{gene} : median P-value of the selected genes. $\rho_{\text{consensus}}$: Pearson correlation between the subnetwork and the consensus network.

We applied six network methods to the GENESIS dataset (Section 2.3.4). As none of the networks examined by LEAN was significant (adjusted P-value < 0.05), we obtained six solutions (Figure 1): one for each of the remaining four gene-based methods, one for SConES GI (which works at the SNP level), and the consensus. These solutions differ in many aspects, making it hard to draw joint conclusions. For starters, the overlap between the genes featured in each solution is quite small (Figure 1B). Another prominent difference is their sizes: the largest solution, produced by HotNet2, contains 440 genes, while heinz’s contained only 4 genes. While SConES GI failed to recover any protein coding gene, by dealing with SNP networks it retrieved four subnetworks in intergenic regions, and another one overlapping an RNA gene (*RNU6-420P*). Their topologies also differ, as measured by the median centrality (Table 2) and the number of connected components (Figure 1D). Only two methods have more than one connected component: SConES, as described above, and HotNet2. HotNet2 produced 135 subnetworks, 115 of which have less than five genes. The second largest subnetwork (13 nodes) contains the two breast cancer susceptibility genes *CASP8* and *BLM*. Lastly, a pathway enrichment analysis (Section 2.4) also showed similarities and differences in the underlying mechanisms. It linked different parts of SigMod’s solution network to four processes: protein translation (including mitochondrial), mRNA splicing, protein misfolding, and keratinization (adjusted P-values < 0.03). Interestingly, dmGWAS solution is also related

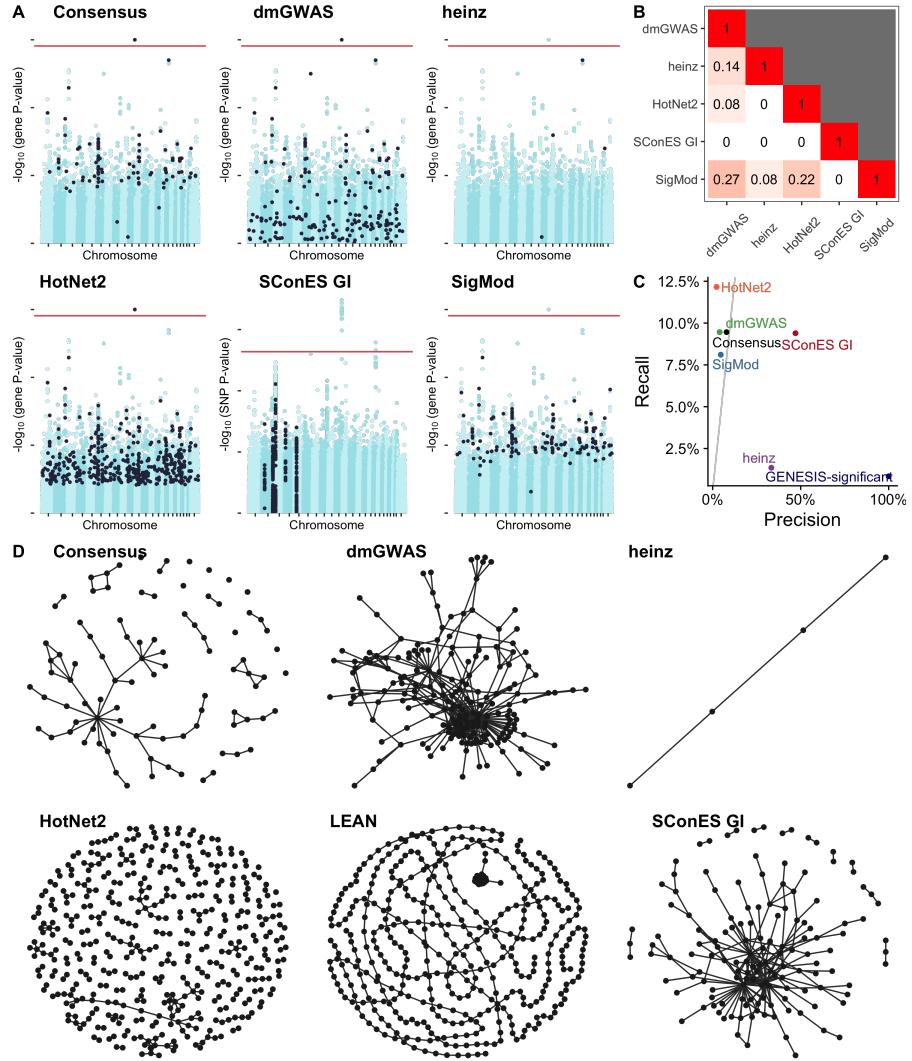

Fig. 1: Overview of the solutions produced by the different network methods (Section 2.3.4) on the GENESIS dataset. As LEAN did not produce any significant gene (adjusted P-value < 0.05), it was excluded. Unless indicated otherwise, results refer to genes, except for SConES GI which are at the SNP-level. **(A)** Manhattan plots of SNPs/genes; in black, the method's solution. The Bonferroni threshold is indicated by a red line (2.54×10^{-7} for SNPs, 1.53×10^{-6} for genes). **(B)** Overlap between the genes selected by each of the methods, measured by Pearson correlation between indicator vectors. **(C)** Precision and recall of the evaluated methods with respect to Bonferroni-significant SNPs/genes in BCAC. For reference, we added a gray line with a slope of 1. **(D)** Solution networks produced by the different methods.

to protein misfolding (*attenuation phase*, adjusted P-value = 0.01). But, additionally, it includes submodules of proteins related to mitosis, DNA damage, and regulation of TP53 (adjusted P-values < 0.05), which match previously known mechanisms of breast cancer susceptibility [41]. As with SigMod, the genes in HotNet2’s solution are involved in mitochondrial translation (adjusted P-value = 1.87×10^{-4}), but also in glycogen metabolism and transcription of nuclear receptors (adjusted P-value < 0.04).

Despite their differences, some common themes exist as well. All obtained solution subnetworks have lower association P-values than the whole PPIN (median P-value $\ll 0.46$, Table 2), despite containing genes with higher P-values as well (Figure 1A). This exemplifies the trade-off between statistical significance and biological relevance. However, there are nuances between solutions: heinz strongly favors genes with lower P-values, while dmGWAS is less conservative (median P-values 0.0012 and 0.19, respectively); SConES tended to select whole LD-blocks; and HotNet2 and SigMod were less likely to select low scoring genes. Additionally, the solution subnetworks present other desirable properties. First, five of them were enriched in known breast cancer susceptibility genes (consensus, dmGWAS, heinz, HotNet2, and SigMod, Fisher’s exact test one-sided P-value < 0.03). Second, the genes in four solution subnetworks display on average a higher betweenness centrality than the rest of the genes, a difference that is significant in four solutions (consensus, dmGWAS, HotNet2, and SigMod, Wilcoxon rank-sum test P-value < 1.4×10^{-21}). This agrees with the notion that disease genes are more central than other non-essential genes [44], an observation that holds in breast cancer (one-tailed Wilcoxon rank-sum test P-value = 2.64×10^{-5} when comparing the betweenness of known susceptibility genes versus the rest). Interestingly, SConES selected SNPs that are also more central than the average SNP (Supplementary table 1), suggesting that causal SNPs are also more central than non associated SNPs.

3.3 A case study: the consensus network

Despite the heterogeneity of the solutions, their shared properties suggest that each method captures different aspects of cancer susceptibility. Indeed, only 20 genes are common to more than two solutions (Supplementary Figure 5A), but encouragingly, the more methods select a gene, the higher its association score to the phenotype (Supplementary Figure 5B). To leverage on their strengths and compensate their respective weaknesses, we built a consensus subnetwork that captures the mechanisms most shared among the solution subnetworks (Section 2.3.4). This subnetwork (Figure 2) contains 93 genes and shares the aforementioned properties of the individual solutions: enrichment in breast cancer susceptibility genes and higher betweenness centrality than the rest of the genes.

A pathway enrichment analysis of the genes in the consensus network also shows similar pathways as the individual solutions. We found two involved mechanisms: *mitochondrial translation* and *attenuation phase*. The former is supported by genes like *MRPS30* (VEGAS P-value = 0.001), which encode a mitochondrial ribosomal protein and was also linked to breast cancer susceptibility [46]. Interestingly, increased mitochondrial translation has been found in cancer cells [58], and

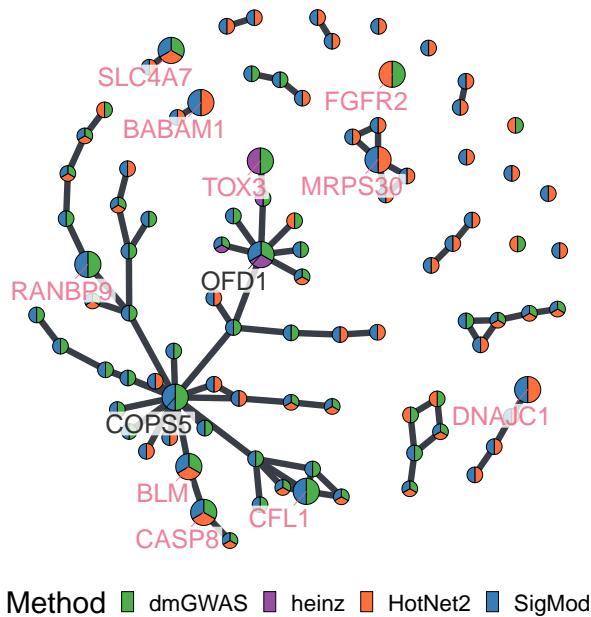

Fig. 2: Consensus subnetwork on GENESIS (Section 2.3.4). Each node is represented by a pie chart, which shows the methods that selected it. We labeled (and enlarged) the two most central genes (*COPS5* and *OFD1*) and those genes that are known breast cancer susceptibility genes and/or significant in the BCAC dataset. The latter ones are also colored in pink.

its inhibition proposed as a therapeutic target. With regards to attenuation phase of heat shock response, it involves three Hsp70 chaperones: HSPA1A, HSPA1B, and HSPA1L. The genes encoding these proteins are all near each other at 6p21, in the region known as HLA. In fact, out of the 22 SNPs that map to any of these three genes, 9 map to all of them, and 4 to two, making hard to disentangle their association. *HSPA1A* was the most strongly associated one (VEGAS P-value = 8.37×10^{-4}).

Topologically the consensus consists of a connected component composed of 49 genes, and multiple smaller subnetworks. Among the latter, 14 of the 93 genes are in subnetworks containing a single gene or two connected nodes, implying that they do not have a consistently altered neighborhood, but are strongly associated themselves and hence picked by two methods. The opposite would be the case of genes with highly centrality in the PPIN, which is weakly anti-correlated with the P-value of association to the disease (Pearson correlation coefficient = -0.26, Supplementary Figure 5D). This suggests that they were selected because they were on the shortest path between two highly associated genes. In view of this, we hypothesize that highly central genes might contribute to the heritability through consistent alterations of their neighborhood, consistent with the omni-genic model of disease [7]. For instance, the most central node in the consensus network is *COPS5*, whose protein is a component of the COP9 signalosome, which regulates multiple signalling pathways. *COPS5* is related to multiple hallmarks of cancer and is overexpressed in multiple tumors, including breast and ovarian cancer [32]. Despite its lack of association in GENESIS or BCAC (VEGAS2v2 P-value of 0.22 and 0.14 respectively), its neighbors in the consensus subnetwork have consistently low P-values (median VEGAS2v2 P-value = 0.006).

3.4 Network methods boost biomarker discovery

We compared the results of different network methods to the European cohort of the Breast Cancer Association Consortium (BCAC) [37], the largest GWAS to date in breast cancer (Section 2.5.3). This comparison is pertinent as, although they do not target the same population(s), we expect a shared genetic architecture at the gene level, at which most examined network methods operate. This shared genetic architecture, together with BCAC's scale (90 times more samples than GENESIS) provides a reasonable counterfactual of what we would expect if GENESIS had a larger sample size. We computed a gene association score on BCAC, in an equivalent way to the one described in Section 2.3.1. The solutions provided by the different network approaches overlap significantly with BCAC findings (Fisher's exact test P-value < 0.019). The gene-based methods achieve comparable precision (2%-25%) and recall (1.3-12.1%) (Figure 1C). However, while SConES GI at the SNP-level achieves a similar recall (8.6%), it shows a much higher precision (47.3%).

3.5 Network methods share limitations

We compared the six network methods in a 5-fold subsampling setting (Section 2.5). Specifically, we measured five properties (Figure 3): size of the solution subnetwork; sensitivity and specificity

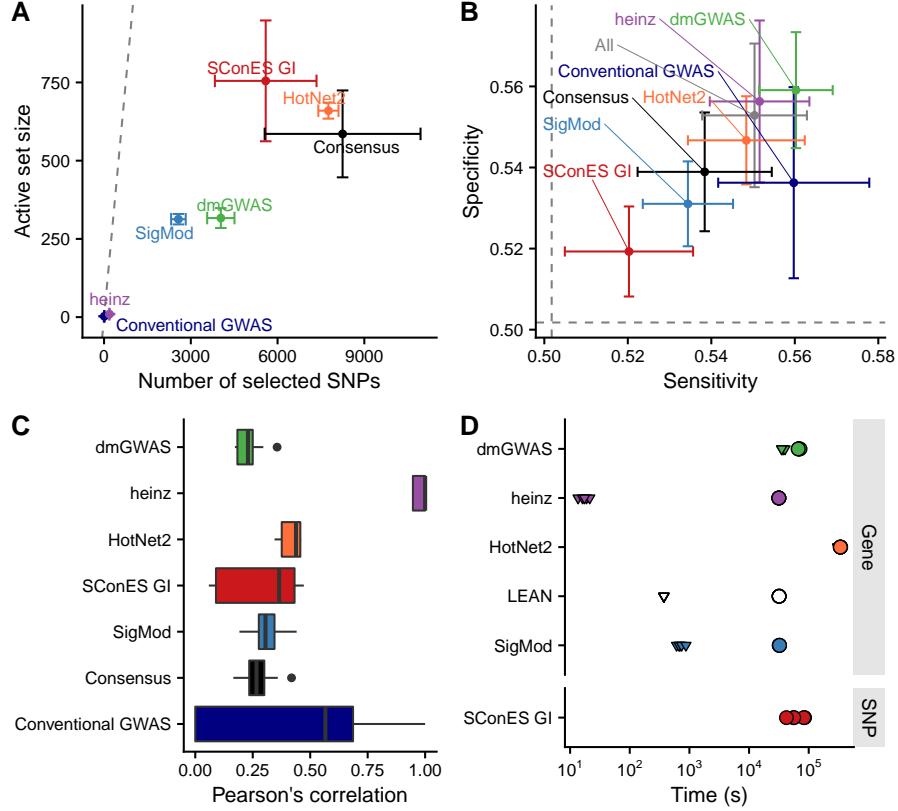

Fig. 3: Comparison of network-based GWAS methods on GENESIS. Each method was run 5 times on a random subset of the samples, and tested on the remaining samples (Section 2.5). As LEAN did not select any gene, it was excluded from all panels except **D**. (**A**) Number of SNPs selected by each method and number of SNPs in the active set found by the classifier. Points are the average over the 5 runs; lines represent the standard error of the mean. A grey diagonal line with slope 1 is added for comparison. For reference, the active set of Lasso using all the SNPs included, on average, 154 117.4 SNPs. (**B**) Sensitivity and specificity on test set of the L1-penalized logistic regression trained on the features selected by each of the methods. In addition, the performance of the classifier trained on all SNPs is displayed. Points are the average over the 5 runs; lines represent the standard error of the mean. (**C**) Pairwise Pearson correlations of the solutions used by different methods. A Pearson correlation of 1 means the two solutions are the same. A Pearson correlation of 0 means that there is no SNP in common between the two solutions. (**D**) Runtime of the evaluated methods, by type of network used (gene or SNP). For gene network-based methods, inverted triangles represent the runtime of the algorithm itself, and circles the total time, which includes the algorithm themselves and the additional 119 980 seconds (1 day and 9.33 hours) that VEGAS2v2 took on average to compute the gene scores from SNP summary statistics.

of an L1-penalized logistic regression classifier on the selected SNPs; stability; and computational runtime. The solution size varies greatly between the different methods (Figure 3A). Heinz produced the smallest solutions, with an average of 182 selected SNPs. The largest solutions come from SConES GI (6 256.6 SNPs), and dmGWAS (4 255.0 SNPs). To determine whether the selected SNPs could be used for patient classification, we computed the performance of the classifier on the *test dataset* (Figure 3B). The different classifiers displayed similarly poor sensitivities and specificities, all in the 0.52 – 0.56 range. Interestingly, the classifier trained on all the SNPs had a similar performance, despite being the only method aiming only at minimizing prediction error.

Another desirable quality of an algorithm is the stability of the solution with regards to small changes in the input (Section 2.5.1). Both heinz and LEAN displayed a high stability in our benchmark, consistently selecting the same genes and no genes over the 5 subsamples, respectively (Figure 3C). Conversely, the other methods displayed similarly low stabilities.

In terms of computational runtime, the fastest method was heinz (Figure 3D), which finds the solution efficiently in a few seconds. HotNet2 was the slowest (3 days and 14 hours on average). Including the time required to compute the gene scores, however, slows down considerably gene-based methods; on this benchmark, that step took on average 1 day and 9.33 hours. Considering that, it took 5 days on average for HotNet2 to produce a result.

3.6 The consensus overcomes the limitations of the individual solutions

As shown above, and despite their similarities, the solutions remain remarkably different. This is due to the particularities of the methods, which directly or indirectly provide information about the dataset. For instance, the fact that LEAN did not provide any biomarkers implies that there is no gene such that both itself and its environment are on average strongly associated with the disease.

In this dataset, heinz’s solution is very conservative, providing a small solution with the lowest median P-value for the subnetwork (Table 2). Due to this parsimonious and highly associated solution, it was the best method to stably select a set of biomarkers (Figure 3C). Its conservativeness stems from its preprocessing step, which models the gene P-values as a mixture model of a beta and a uniform distribution, controlled by an FDR parameter. Due to the limited signal at the gene level in this dataset (Supplementary Figure 2B), only 36 of them are retain a positive score after that transformation. Yet, this small solution does not provide much insight into the biology of cancer. Importantly, it ignores genes that are associated to cancer in this dataset like *FGFR2*.

On the other end of the spectrum, we have large solutions provided by dmGWAS, HotNet2, and SigMod. dmGWAS’ subnetwork is the least associated subnetwork on average. This is due to the greedy framework it uses, which has a bias for larger solutions [42]. This framework considers all nodes at distance 2 of the examined, and accepts weakly associated genes if they are linked to another, strongly associated one. This is exacerbated when the results of successive greedy searches are aggregated, leading to a large, tightly connected cluster of unassociated genes (Figure 4A). SigMod displays the same tendency, as the most central genes are the least associated to the disease

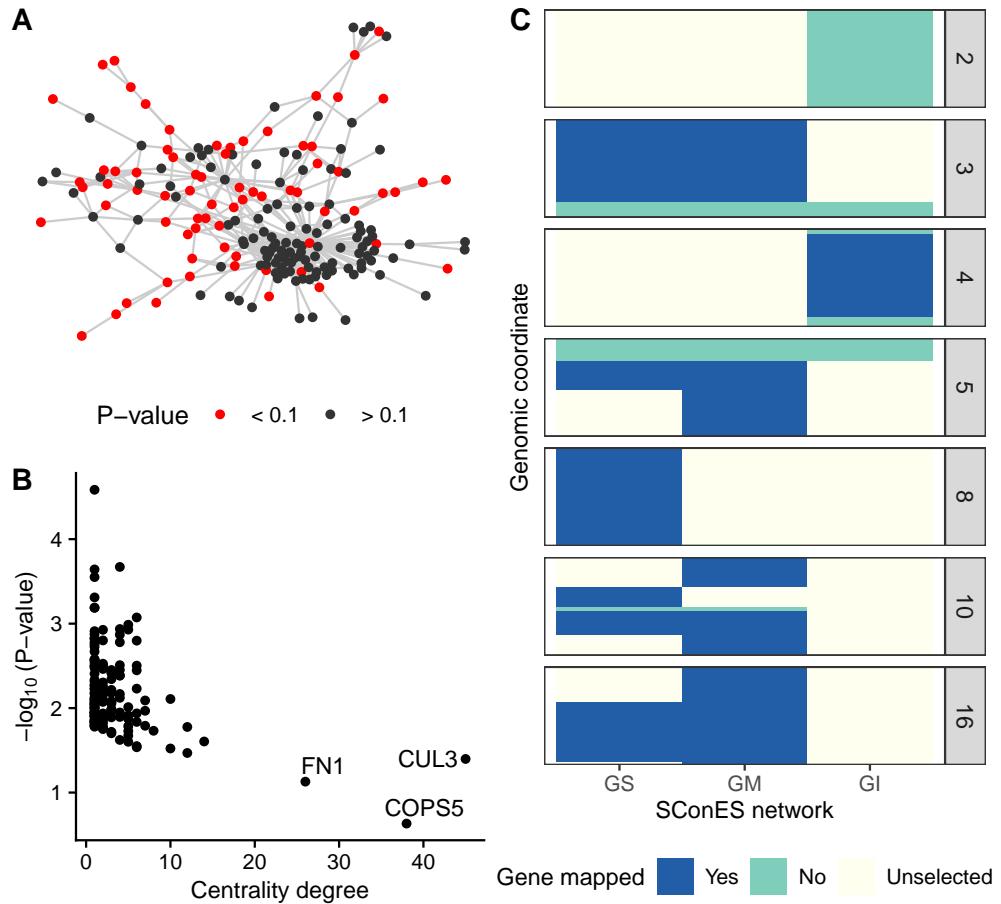

Fig. 4: Drawbacks encountered when using network guided methods. **(A)** dmGWAS solution subnetwork. Genes with a P-value < 0.1 are highlighted in red. **(B)** Centrality degree and $-\log_{10}$ of the VEGAS2v2 P-value for the nodes in SigMod solution subnetwork. **(C)** Genomic regions where either SConES GS, GM or GI select SNPs.

(Figure 4B). This relatively low signal-to-noise ratio combined with the large solution requires additional analyses to draw conclusions, such as enrichment analyses. In the same line, HotNet2’s subnetwork is even harder to interpret, being composed of 440 genes divided into 135 subnetworks. Lastly, SigMod misses some of the most strongly associated, breast cancer susceptibility genes in the dataset, like *FGFR2* and *TOX3*.

By virtue of using a SNP subnetwork, SConES analyzes each SNP in their context. It therefore selects SNPs in genes none of whose interactors are associated to the disease, as well as SNPs in non-coding regions or in non-interacting genes. In fact, due to linkage disequilibrium, such genes are favored by SConES, as selecting SNPs in an LD block which overlaps with a gene favors selecting the rest of the gene. This might explain why SConES produces similar results on the GS and GM networks, heavily affected by linkage disequilibrium (Supplementary Figure 3). On the other hand, SConES penalizes selecting SNPs and not their neighbors. This makes it conservative regarding SNPs with many interactions, for instance those mapped to hubs in the PPIN. For this reason, SConES GI did not select any protein coding gene, despite selecting similar regions as SConES GS (Figure 4C). In fact SConES GS and SConES GM select regions related to breast cancer, like 16q12 (*TOX3*, Section 3.1), 3p24 (*SLC4A7/NEK10* [1]), 5p12 (*FGF10, MRPS30* [46]), and 10q26 (*FGFR2*, Section 3.1). On top of that only SConES GS selects region 8q24 (*POU5F1B* [8]). We hypothesize that the lack of results on the PPIN network of SConES GI and LEAN are due to the same cause: the absence of joint association of a module. Although in the case of SConES other hyperparameters could lead to a more informative solution (e.g. lower λ , Section 2.3.4), it is unclear what is the best strategy to find them. In addition, due to the iCOGS SNP array design, the genome of GENESIS participants has not been unbiasedly surveyed: some regions are fine-mapped — which might distort gene structure in GM and GI networks — while others are under studied — hindering the accuracy with which the GS network captures the genome structure.

3.7 Adjusting for instability leads to similar conclusions

Most of the network methods, even the consensus, were highly unstable, raising questions about the *veracity reliability* of the results. We built a *new, stable* consensus network using the 30 solutions from *obtain by running* the 6 different methods on 5 different splits *each* containing 80% of the data (Section 2.5). Such a network *would be expected to capture* the subnetworks more often found altered, and hence should be more resistant to noise. We used only genes selected in at least 7 of the settings (*percentile 99%* [CA: I’m reluctant to talk about percentiles here, as the genes aren’t ranked with each a different value – I’d rather say “corresponding to selecting 1% of the genes” or something like that]). The resulting stability-based consensus was composed of 68 genes. This network shares most of the properties of the consensus: breast cancer susceptibility genes are overrepresented ($P\text{-value} = 3 \times 10^{-4}$), as well as genes involved in mitochondrial translation and the attenuation phase (adjusted P -values 0.001 and 3×10^{-5} respectively); the selected genes are more central than average ($P\text{-value} = 1.1 \times 10^{-14}$); and *19 of them are isolated* [CA: what property of the previous consensus network is this?].

However, the shared global properties of the network although this new network exhibits similar global properties as the previous one, the lack of stability results in different genes being selected. In this case, the most central gene of the network is *CUL3*, which is absent from the previous consensus network. Indeed, *CUL3* has a low association score in both GENESIS and BCAC (P-values of 0.04 and 0.26, respectively). *CUL3* is a component of Cullin-RING ubiquitin ligases. It impacts the protein levels of multiple genes relevant for cancer progression [14], and its overexpression was also linked to increased sensitivity to carcinogens [36].

4 Discussion

In recent years, the ability of GWAS to unravel the mechanisms leading to complex diseases has been called into question [7]. The omnigenic model proposes that gene functions are interwoven with each other in a dense co-function network. The practical consequence is that larger and larger GWAS will lead to the discovery of an uninformative wide-spread pleiotropy. Other than such problems In addition, discovery in GWAS is hindered by a conservative statistical framework. Network methods tackle both these two issues by using both the association score and an interaction network to consider take into consideration the biological context of each of the genes and SNPs. Based on what could be considered diverse interpretations of the omnigenic model, several methods for network-guided biomarker discovery have been proposed in recent years. In this article we evaluate the relevance of six network methods by examining a GWAS dataset on familial breast cancer.

Most of these methods produced a relevant subset of biomarkers, recapitulating known breast cancer susceptibility genes. On median In general [CA: I don't think "On median" exists, unfortunately], the selected genes and SNPs were more central than average, in accordance with the observation that disease genes are more relatively central [44]. However, very central nodes are also more likely to be connecting a given random pair of nodes, making them more likely to be selected by these network methods. Hence, further work is needed to characterize the impact of centrality on these methods' outputs. Despite their similarities, the solutions were notably different. At one end of the spectrum, SConES and heinz preferred small, highly associated solutions, providing a conveniently short list of biomarkers, at the expense of not shedding much light on the etiology of the disease. On the other end, SigMod and dmGWAS gravitate towards larger, less associated solutions which provide a wide overview of the biological context. While this deepens our understanding of the disease and provide biological hypotheses, they require further analyses, which might deter unexperienced practitioners. HotNet2 balances both approaches at the expense of producing the largest solution: a constellation of many, highly associated, small subnetworks. Despite these differences, all solutions are equally bad at discriminating cases from controls. In addition, all methods are remarkably unstable, yielding different solutions for slightly different inputs. This might partly be caused by the instability of the P-values themselves in low statistical power settings [25]. Hence, heinz's conservative transformation of P-values, which favors only the most

extreme ones, leads to improved stability. Another source of instability might be the redundancy inherent to biological networks. We built a stable consensus, which accounts for that instability. Encouragingly, this network shared the same biological and topological properties as the individual solutions, despite the few genes in common due to instability. Overall, this supports that instability might be caused by redundant but equivalent biological mechanisms, and hence it validates the conclusions obtained on the individual solutions and the consensus. [CA: This comes too early, the next paragraph discusses why and how we built the consensus network and this bit should only arrive afterwards] [CA: I think we need to discuss this. Why aren't we able to classify cases from controls (multiple non-genetic factors, disease heterogeneity...)? Why is our approach still useful if we aren't, in fact, discovering biomarkers? (it points at relevant pathways, etc)]

To overcome the limitations of the individual methods while exploiting their strengths, we propose combining them into a consensus subnetwork. We use a straightforward aggregation, including any node that was recovered by at least two methods. The resulting network is a synthesis of the altered mechanisms: it is smaller than the largest solutions (HotNet2, SigMod and dmGWAS), which makes it more manageable, and includes the majority of the strongly associated smaller solutions (SConES and heinz). The consensus subnetwork captures mechanisms and genes known to be related to cancer, recovering known breast cancer susceptibility genes as well as genome regions associated to breast cancer susceptibility. However, thanks to its smaller size and its network structure, it provides compelling hypotheses of non-canonical mechanisms involved in carcinogenesis, like mitochondrial translation and chaperone activity.

The strength of network-based analyses comes from leveraging prior knowledge to boost discovery. In consequence, they show their shortcomings in front of understudied genes, especially those not in the network. Out of the 32 767 genes that we can map the genotyped SNPs to, 60.7% (19 887) are not in the protein-protein interaction network. The majority of those (14 660) are non-coding genes, mainly lncRNA, miRNA, and snRNA (Supplementary Figure 6). Yet, RNA genes like *CASC16* are associated to breast cancer (Section 3.1), reminding us of the importance of using networks beyond coding genes. In addition, even protein-coding genes linked to breast cancer susceptibility [1], like *NEK10* (P -value 1.6×10^{-5} , located near *SLC4A7*) or *POU5F1B*, were absent from the network. However, on average protein-coding genes absent from the PPIN are less associated with this phenotype (Wilcoxon rank-sum P -value = 2.79×10^{-8} , median P -values of 0.43 and 0.47). As we are using interactions from high-throughput experiments, such difference cannot be due to well-known genes having more known interactions. As disease genes tend to be more central [44], we hypothesize that it is due to interactions between central genes being more likely. It is worth noting that network approaches that do not use PPIs, like SConES GS and GM, did recover SNPs in *NEK10* and *CASC16*. Moreover, both SConES GM and GI recovered intergenic regions, which might contain key regulatory elements [22] and, yet, are excluded from gene-centric approaches. This shows the potential of SNP networks, in which SNPs are linked when there is evidence of co-function, to perform network-guided GWAS even in the absence of gene-level interactions. Lastly, all the methods rely heavily on. In Section 3.3 we highlight ambiguities that appear when genes overlap or are in linkage disequilibrium. In fact, the presented case is paradigmatic, since the genes

are in the most gene-dense region of the genome [56]. Network methods are prone to selecting such genes when they are functionally related, and hence interconnected in the network, but might be more resilient to them when the overlapping genes are unrelated. More targeted mappings of SNPs to genes (e.g. eQTLs, SNPs associated to the expression of a gene), altogether with a stringent LD pruning, might address such problems.

As not all databases compile the same interactions, the choice of the PPIN determines the final output. In this work we used exclusively interactions from HINT from high-throughput experiments. This responds to concerns about adding interactions identified in targeted studies and prone to a “rich getting richer” phenomenon: popular genes have a higher proportion of their interactions described [12, 16]. Their presence might bias the results of the presented methods, as they change the topology of the network by adding nodes closer to other nodes than average. On the other hand, Huang et al. [26] found that the best predictor of the performance of a network for disease gene discovery is the size of the network, which supports using the largest amount of interactions. When we compared the impact of using a larger network containing interactions from both high-throughput experiment and the literature (Section 2.3.3), we found that for most of the methods it did not greatly change the size or the stability of the solution, the classification accuracy, or the runtime (Supplementary Figure 7). This supports using only interactions from high-throughput experiments, which produces apparently similar solutions and avoids falling into “circular reasonings”, where the best known genes are artificially pushed into the selected solutions.

A crucial step for the gene based methods is the computation of the gene score. In this work we used VEGAS2v2 [38] due to the flexibility it offers to use user-specified gene annotations. However, it presents known problems (selection of an appropriate percentage of top SNPs, long runtimes and P-value precision limited to the number of permutations [40]), and other algorithms [40, 27, 53] might have more statistical power. Another important decision is how to handle LD in a GWAS. VEGAS2v2 accounts for LD patterns, and hence an LD pruning step would not impact gene-based network methods, although it would speed up VEGAS2v2’s computation time. With regards to SConES, less SNPs would lead to simpler SNP networks and, possibly, shorter runtimes. However, as mentioned in Section 3.6, LD patterns seem paramount to SConES’ solutions, and an LD pruning step could potentially alter them.

In order to produce the consensus network, we had to face the different interfaces, preprocessing steps, and unexpected behaviors of the various methods. To facilitate that other authors apply them to new datasets and aggregate their solutions, we built six nextflow pipelines [17] with a consistent interface and, whenever possible, parallelized computation. They are available on GitHub: <https://github.com/hclimente/gwas-tools>. Importantly, those methods that had a permissive license were compiled into a Docker image for easier use, which is available on Docker Hub hclimente/gwas-tools.

Author contributions

H.C-G. conducted all the final analyses and wrote the manuscript. C.L. conducted analyses using LEAN, Sigmod, and dmGWAS, and provided technical and scientific help and feedback. F.L. and N.A. provided feedback on the analyses and the manuscript. C-A.A. supervised the project.

Funding and acknowledgments

This project was supported by funding from Agence Nationale de la Recherche (ANR-18-CE45-0021-01) and from the European Union's Horizon 2020 research and innovation program (Marie Skłodowska-Curie [666003]). Financial support for GENESIS resource and genotyping was provided by the Ligue Nationale contre le Cancer (grants PRE05/DSL, PRE07/DSL, PRE11/NA), the French National Institute of Cancer (INCa grant b2008-029/LL-LC) and the comprehensive cancer center SiRIC (Site de Recherche Intégrée sur le Cancer: INCa-DGOS-4654).

1 Supplementary materials

Table 1: Summary statistics on the results of SConES on the three SNP-SNP interaction networks. The first row within each block contains the summary statistics on the whole network.

Network	SNPs	Edges	Subnetworks	Betweenness	\hat{P}_{SNP}
GS	197 083	197 060	-	2.03×10^7	0.49
SConES GS	1 590	1 585	5	2.52×10^7	0.023
GM	197 083	6 442 446	-	3.99×10^6	0.49
SConES GM	1 692	177 611	5	4.40×10^6	0.055
GI	197 083	28 733 720	-	1.46×10^6	0.49
SConES GI	408	539	5	9.33×10^6	0.076

Betweenness: mean betweenness of the selected SNPs in the corresponding full network. \hat{P}_{SNP} : median P-value of the selected SNPs.

Table 2: Summary statistics on the results of multiple network methods on the gene-gene interaction network. The first row contains the summary statistics on the whole network.

Network	Genes	Edges	Betweenness	\hat{P}_{gene}	$\rho_{consensus}$
SConES GS	5	0	9 805	2.7×10^{-5}	0.19
SConES GM	28	2	4 267	0.067	0.12

Betweenness: mean betweenness of the selected genes in the full network. \hat{P}_{gene} : median P-value of the selected genes; $\rho_{consensus}$: Pearson correlation with the consensus network.

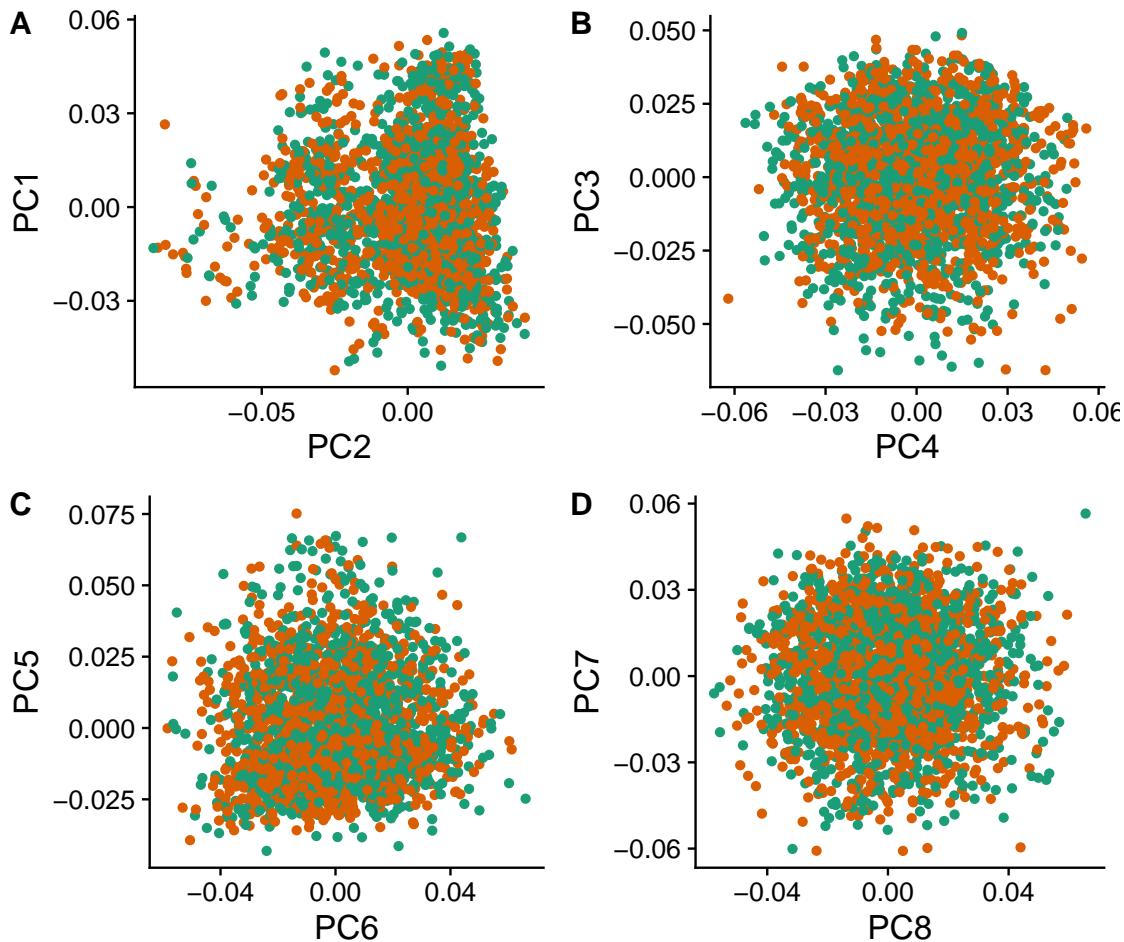

Fig. 1: GENESIS shows no differential population structure between cases and controls.
(A,B,C,D) Eight main principal components computed on the genotypes of GENESIS. Cases are colored in green, controls in orange.

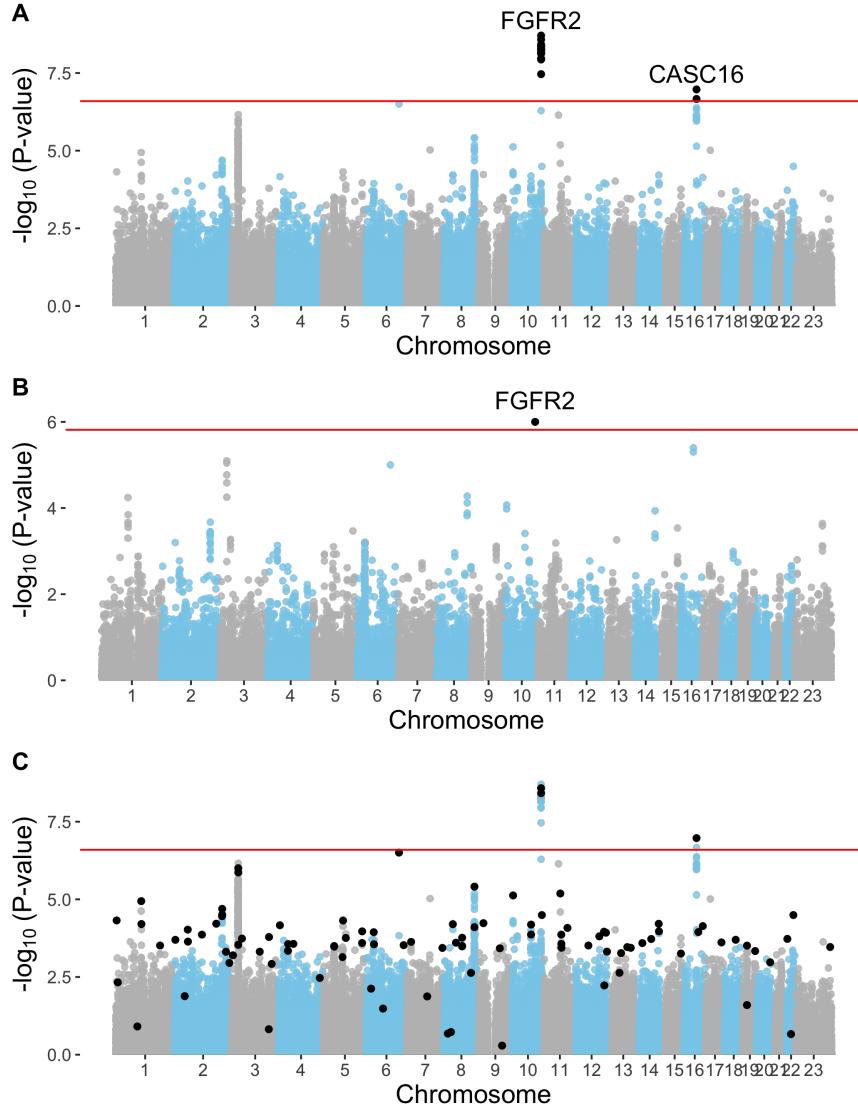

Fig. 2: Association in GENESIS. The red line represents the Bonferroni threshold. **(A)** SNP association, measured from the outcome of a 1 d.f. χ^2 allelic test. Significant SNPs that are within a coding gene, or within 50 kilobases of its boundaries, are annotated. The Bonferroni threshold is 2.54×10^{-7} . **(B)** Gene association, measured by P-value of VEGAS2v2 [38] using the 10% of SNPs with the lowest P-values. The Bonferroni threshold is 1.53×10^{-6} . **(C)** SNP association as in panel (A). The SNPs in black are selected by a L1-penalized logistic regression (Section 2.5.2, $\lambda = 0.03$).

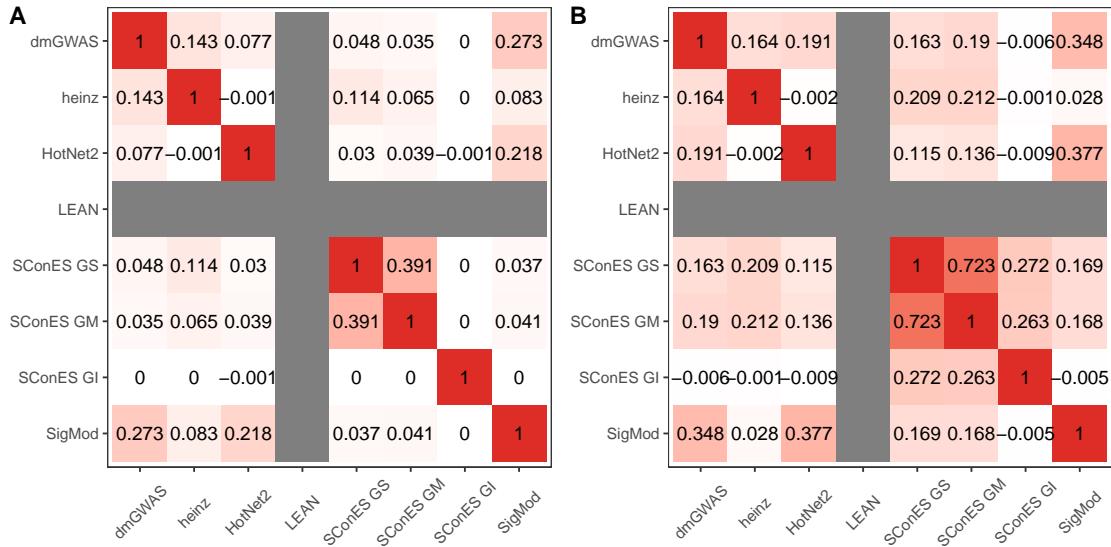

Fig. 3: Pearson correlation between the different solution subnetworks. **(A)** Correlation between selected SNPs. **(B)** Correlation between selected genes. In general, the solutions display a very low overlap.

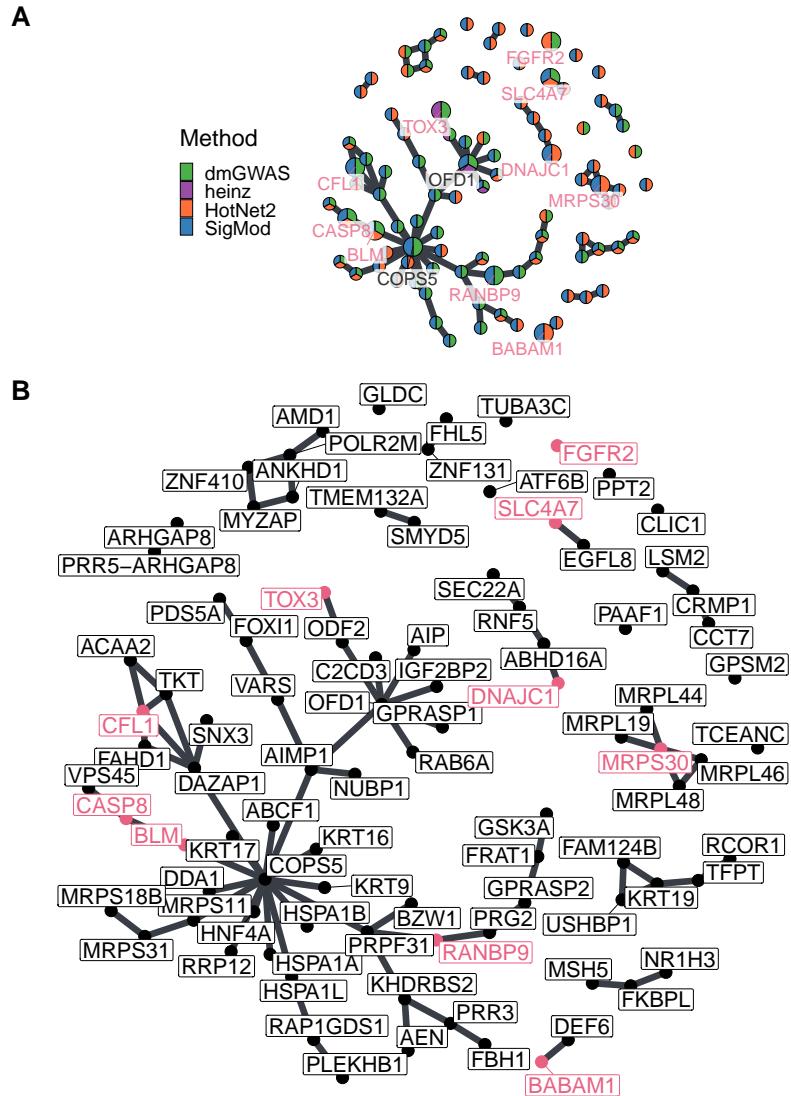

Fig. 4: Consensus subnetwork on GENESIS (Section 2.3.4). **(A)** Each node is represented by a pie chart, which shows the methods that selected it. We labeled (and enlarged) the two most central genes (*COPS5* and *OFD1*) and those genes that are known breast cancer susceptibility genes and/or significant in the BCAC dataset. The latter ones are also colored in pink. This panel is identical to Figure 2. **(B)** Same network, but every gene name is indicated.

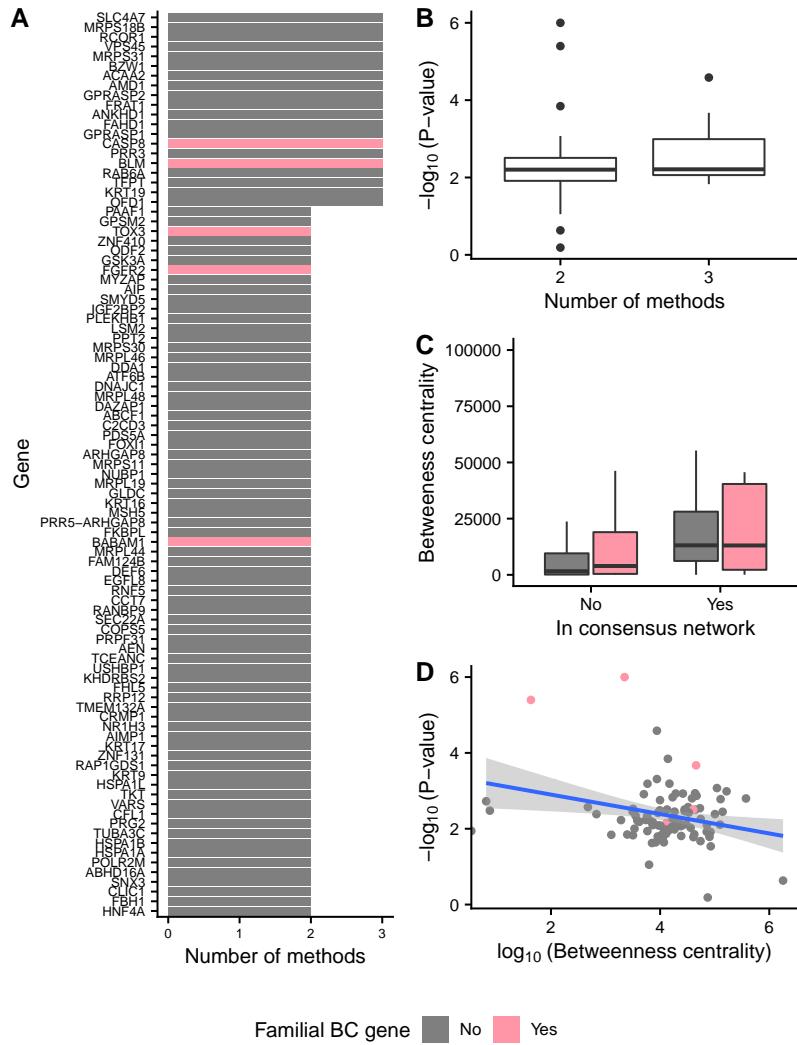

Fig. 5: Genes on the consensus network. Breast cancer susceptibility genes are colored in pink; the rest are colored in grey. **(A)** Number of methods selecting every gene in the subnet-work. **(B)** VEGAS P-values of association of the genes, with regards to the number of methods that selected them. **(C)** Comparison of betweenness centrality of the genes in the consensus network and the other genes in the PPIN and not in the consensus network. To improve visualization, we removed outliers. **(D)** Relationship between the \log_{10} of the betweenness centrality and the $-\log_{10}$ of the VEGAS P-value of the genes in the consensus network. The blue line represents a fitted generalized linear model.

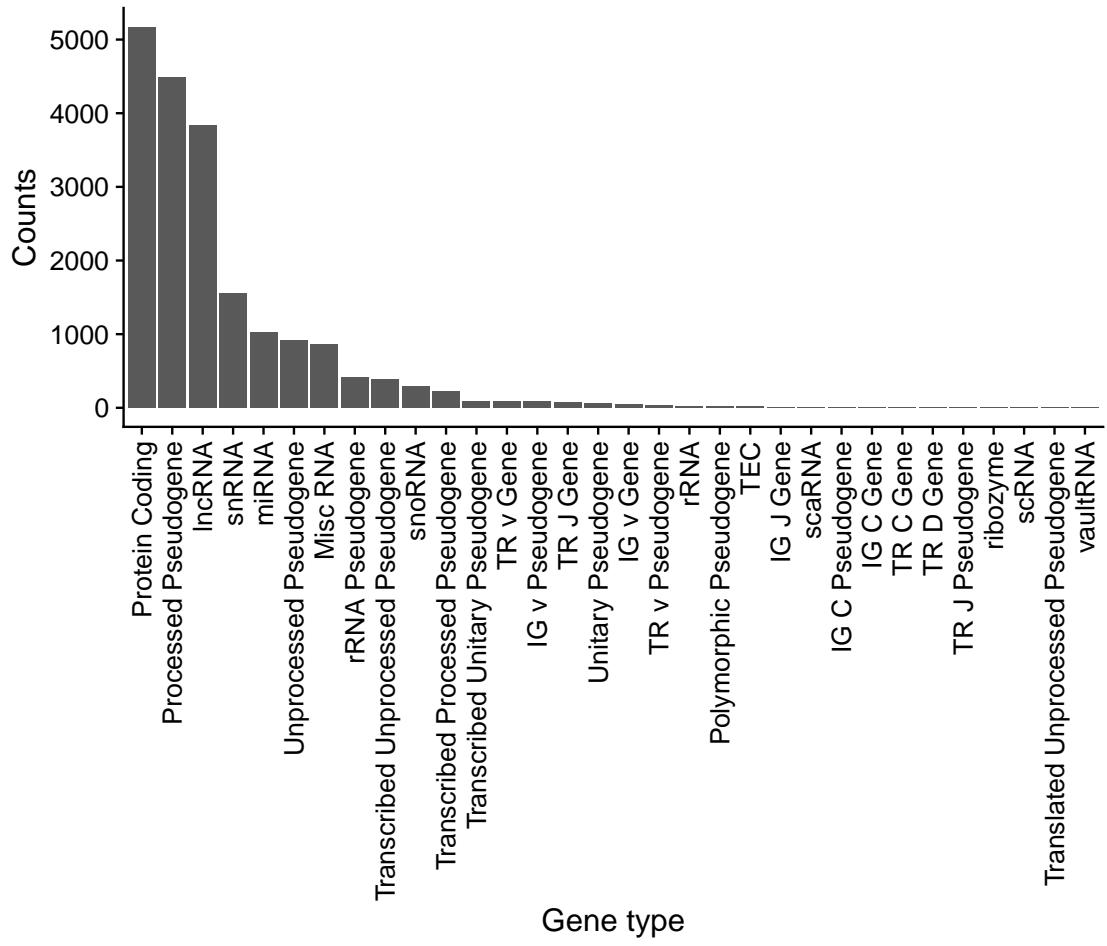

Fig. 6: Biotypes of genes from the annotation that are not present in the HINT protein-protein interaction network.

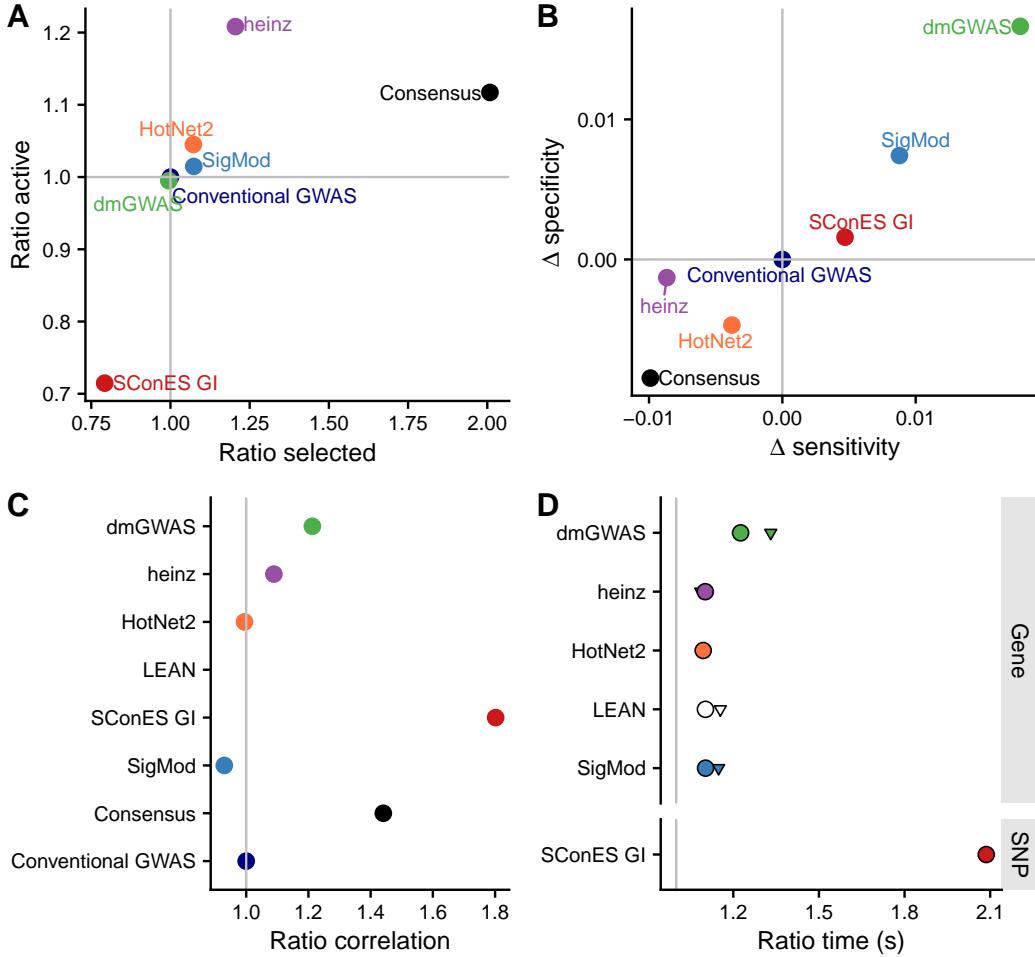

Fig. 7: Comparison of benchmark on high-throughput (HT) interactions to benchmark on both high-throughput and literature curated interactions (HT+LC). Grey lines represent no change in the statistic between the benchmarks (1 for ratios $\text{mean}(\text{HT}) / \text{mean}(\text{HT} + \text{LC})$, 0 for differences $\text{mean}(\text{HT}) - \text{mean}(\text{HT} + \text{LC})$). **(A)** Ratios of the selected features between both benchmarks and of the active set. **(B)** Shifts in sensitivity and specificity. **(C)** Shift in Pearson correlation between benchmarks. **(D)** Ratio between the runtimes of the benchmarks. For gene network-based methods, inverted triangles represent the ratio of runtimes of the algorithms themselves, and circles the total time, which includes the algorithm themselves and the additional 119 980 seconds (1 day and 9.33 hours) that VEGAS2v2 took on average to compute the gene scores from SNP summary statistics. In general, adding additional interactions slightly improves the stability of the solution, but increases the solution size, has mixed effects on the sensitivity and specificity, and impacts negatively the required runtime of the algorithms.

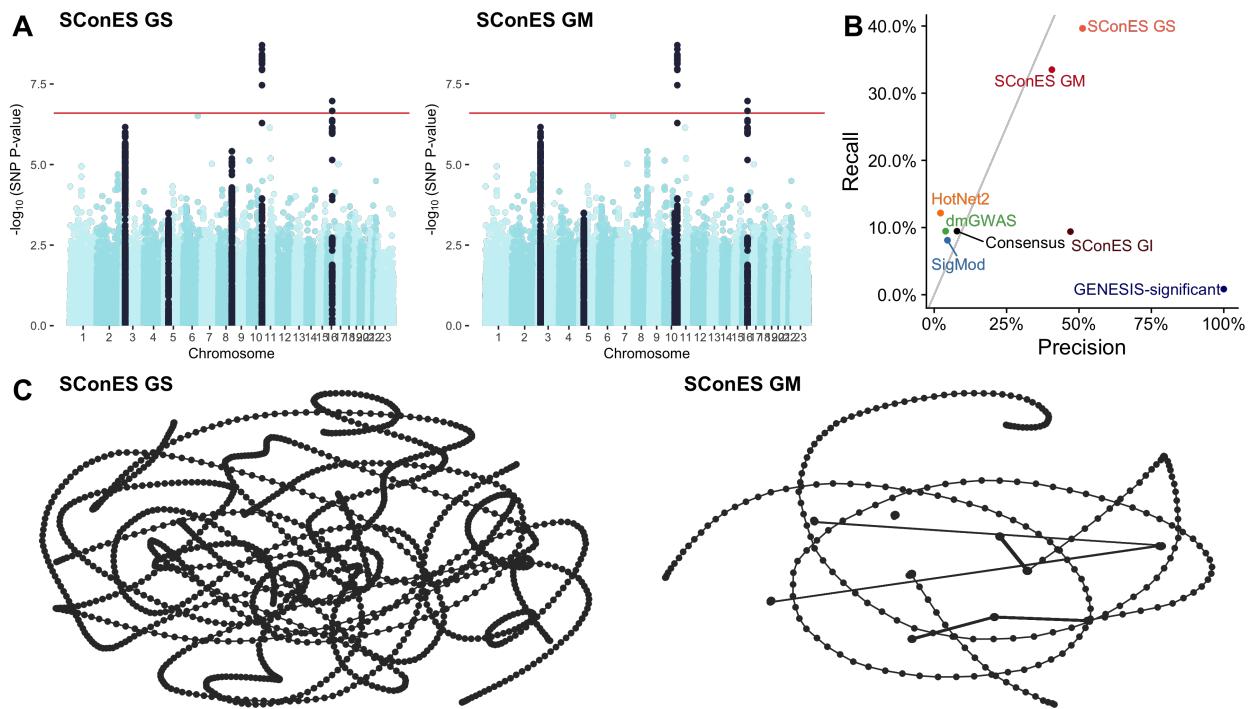

Fig. 8: Overview of the solutions produced by the SConES on the GS and GM networks (Section 2.3.3) on the GENESIS dataset. (A) Manhattan plots of SNPs; in black, the method's solution. The Bonferroni threshold (2.54×10^{-7}) is indicated by a red line. (B) Precision and recall of the evaluated methods with respect to Bonferroni-significant SNPs (SConES) or genes (other methods) in BCAC. For reference, we added a gray line with a slope of 1. (C) Solution networks.
